EHPH Statement 5: Patient Safety and Quality Assurance.

ABSTRACT

Objective In intensive care units numerous drugs have to be infused simultaneously, resulting in incompatibility. Propofol is formulated as a lipid emulsion and it is well known that electrolytes can affect the stability of an emulsion system. Our goal was to evaluate and to compare the physical compatibility of three commercial propofol lipid emulsions of different manufacturers, mixing them with the most commonly used crystalloids in intensive care units.

Methods Simulated Y-site administration was accomplished by mixing the 2% MCT/LCT propofol emulsions with the commonly used crystalloids in the intensive care unit in a 1:1 ratio in a polypropylene syringe. The aliquot samples were evaluated immediately and at 15, 30, 60 and 120 min after preparation by visual observation, pH and droplet size measurement.

Results There was no emulsion breakdown or any visible change during the study period. Mixing the propofols with crystalloids, 10% magnesium sulphate or 10% potassium chloride there was no significant change in the droplet size compared with the original propofol emulsions. A slight alteration in droplet size was noticed in a few of the propofol samples, when magnesium, potassium or both were the secondary additives to the crystalloids, but this is not considered clinically relevant.

Conclusion The physical properties of emulsions are determined by component, therefore the compatibility data in literature has to be evaluated prudently. All three commercially available MCT/LCT propofol emulsions are considered physically compatible with the tested crystalloids.

INTRODUCTION

Propofol is a widely used sedative agent for the sedation of intubated, mechanically ventilated patients in the intensive care units (ICUs). Its popularity is due to rapid onset, short duration of action and minimal side effects.¹

Since propofol is insoluble in water and it cannot be administered as aqueous salt, it is formulated as an oil-in-water lipid emulsion. Diprivan (AstraZeneca) was the first approved injectable propofol emulsion and it has become one of the most commonly used worldwide. This formulation consists of propofol, soybean oil (long-chain triglycerides, LCTs), egg-yolk lecithin, glycerol, water, EDTA and sodium hydroxide to adjust the pH to 7–8.5.²

In another formulation (Gensia Sicor Pharmaceuticals), EDTA was replaced with metabisulphite. Since metabisulphite only dissolves in acidic media, the pH of this formulation is adjusted to 4.5–6.5.

This lower pH affects the stability and other physical characteristics of the emulsion.³ Metabisulphite has been also reported to support lipid peroxidation in propofol emulsion and to cause allergic reactions.⁴ Currently available newer formulations of propofol (B.Braun, Fresenius Kabi) are preservative-free and contain mixed medium chain triglycerides (MCTs)—long chain triglycerides (LCTs).^{5,6} It was reported that this formulation did not affect the pharmacokinetics or pharmacodynamics of propofol and was found to cause less pain on injection.^{7,8}

Lipid macroemulsions are thermodynamically unstable, therefore maintaining long-term stability is a major challenge. The stability of an emulsion depends ultimately on the interfacial tension and the droplet size. Other contributing factors to stability of the emulsion are density, viscosity, zeta potential and temperature. Furthermore, type of the emulsifier component, applied lipids and pH can influence the physicochemical stability of lipid emulsions.⁹ Any change in the structure of emulsion can lead to different types of emulsion instability eg. flocculation, creaming, coalescence or breaking.¹⁰

Critically ill patients are treated with complex intravenous medications. The majority of the patients admitted to the ICU requires sedation for which mainly propofol is used. The most commonly used medications, beside propofol, are the opioid analgesics, antibiotics, vasopressors, antihypertensive agents. The use of crystalloids are also essential to ensure the adequate hydration of patients. Crystalloids are aqueous solutions of mineral salts or other water-soluble molecules. Despite of the presence of multilumen central vein catheter (CVC), different medications, including crystalloids, are often co-infused in the same line which may produce the likelihood of incompatibility. Incompatibility can involve precipitation, ionic reactions, evolution of gas and denaturation of biological molecules. This can cause decreased drug effectiveness or increased microparticle load with well-documented consequences, such as therapeutic failure, catheter occlusion or embolism.^{11–14} It has been previously reported that fat embolism occurred, when propofol was mixed with lidocaine.¹⁵ The compatibility of propofol with other drugs has been investigated by other authors, however, in these studies the LCT formulations of propofol (Diprivan and its generics) were tested, not the newer MCT/LCT formulation.¹⁶ To our best knowledge, there is no published data concerning the compatibility of MCT/LCT propofol and crystalloids, furthermore mixing of propofol with other

infusions is not recommended by the manufacturers.^{5 6 17} Despite the warnings of manufacturer the co-administration of infusions is common in the clinical practice because of limited intravenous access. Our goal was to evaluate and to compare the physical compatibility of three commercial MCT/LCT propofol emulsions from different manufacturers, mixing them with the most commonly used crystalloids in the intensive care. Based on our stability results, we make conclusions on the use of mixtures in clinical practice.

MATERIAL AND METHODS

For this study we used three different propofol products and four crystalloids that are available on the Hungarian market. The propofol emulsions are manufactured by B.Braun (BB), Fresenius-Kabi (FK) and UAB Norameda (UAB). In the ICU 20 mg/mL (2%) propofol is used, therefore we decided to investigate this concentration. Compositions of commercially available propofol products and Diprivan (AstraZeneca) (which is not available on the Hungarian market) are compared in table 1. The electrolyte content of crystalloids are listed in table 2.

Sample preparation

The study samples were static admixtures of crystalloids and propofol with a ratio of 1:1 (v/v). First, a 5 mL sample of 2% propofol emulsion was combined individually with 5 mL of crystalloids, 5 ml of 10% magnesium sulphate (Pharmmagist Kft., Budapest) or 5 ml 10% potassium chloride (Pharmmagist Kft., Budapest) in a colourless 20 mL polypropylene syringe (B.Braun, Omnifix). Second, eligible amount of 10% magnesium sulphate and/or 10% potassium chloride was

added to each crystalloids as a secondary additive making the final concentration 4 mg/mL. After this, 5 mL of samples were mixed with 5 mL of propofol emulsions in the syringes. In all cases the air was evacuated from the syringes, then the content was mixed by shaking. The samples were subsequently stored at room temperature (25°C) and in daylight in the laboratory.

Methods

The pH and the mean droplet size distribution of all three propofols were measured on samples taken out of the original package. For the analysis of admixtures, 2 mL of mixed samples were taken out of the syringes immediately and at 15, 30, 60 and 120 min after preparation, and the following two measurements were done with all samples: pH and droplet size measurement. The pH values of samples were determined by a portable pH meter equipped with an inserting probe (Testo 206-pH2, Testo, Lenzkirch, Germany). The pH meter was calibrated using a solution of pH 4 and pH 7 before each measurement sample series. The volume based drop size distribution of the emulsions was measured by laser diffraction (Mastersizer 2000, Malvern Instruments Ltd., Worcestershire, UK) at room temperature (25°C) with the following parameters: 300 RF lens; small volume dispersion unit (2000 rpm); refractive index for dispersed particles 1.596; refractive index for dispersion medium 1.330. The size analysis was repeated three times. Glycerol-water 1:37 was used as dispersant medium. In all cases, the volume weighted drop size distributions, d(0.1), d(0.5), and d(0.9) (where for example d(0.5) is the maximum particle diameter below which 50% of the sample volume exists—also known as the median particle size by volume) were determined and evaluated. During the study the samples were inspected visually with unaided eye for obvious degradation of the emulsion and/or oil separation.

RESULTS

There was no considerable difference in the pH of the three propofols when measured after being taken out of the original vials. After mixing with crystalloids, the pH of samples were, according to the original pH of crystalloids, between 4.37–7.31 (figures 1 and 2). The admixtures of the Sterofundin B (SFB) and Sterofundin G (SFG) resulted in the lowest pH, due to the fact that these infusions originally had a lower pH, which is needed to prevent decomposition of their glucose component during autoclaving. The mean droplet size of all three propofols were measured and taken out of their original packages resulting in no significant difference: BB 0.133 µm, FK 0.136 µm and UAB 0.135 µm, respectively. The effect of crystalloids to droplet size of propofol emulsion are summarised in figure 3. Mixing all three propofols with 10% magnesium sulphate or 10% potassium chloride there was no change in visual appearance and in droplet size despite high electrolyte concentration. Furthermore, there was no alteration when mixing the propofols with crystalloids.

When adding potassium chloride to Ringerfundin (RF) and SFB there was a slight alteration in the droplet size of propofol of FK and there was no detectable visible change in any of the mixed samples.

The addition of both magnesium and potassium to the crystalloids did not result in change in the droplet size when it was mixed with the propofol of B or UAB. There was considerable increase in the droplet size when the propofol of FK was mixed with RF and potassium and magnesium was added, but the droplet size remained below 1 µm.

DISCUSSION

Lipid emulsions are thermodynamically unstable, therefore their stability is important for safely administering infusions. Physical incompatibility, precipitation of particles or growth of droplet, is more relevant for Y-site administration than chemical incompatibility, because of the short contact time.¹¹ Both precipitates

and enlarged oil droplets can cause fatal emboli and harm to the liver and lungs.^{11–14} Furthermore, the droplet surface area decrease can cause alteration in the release of propofol in vivo due to the enlarged droplet size.¹⁸ The quality and safety of lipid emulsions has been identified, uniquely among pharmacopoeia, in the United States Pharmacopoeia (USP) since 2007. The USP standards require that the volume weighted percentage of fat with droplet diameter above 5 µm (PFAT5) should be ≤ 0.05%.¹⁹ Although lipid emulsions have been in clinical use for more than 50 years there is no standardised procedure or consensus to which test should be accomplished to evaluate their compatibility. Therefore, various methods have also been used to investigate their stability, most commonly the visual observation, pH, droplet size and zeta potential measurement. According to a recent study the best practice testing compatibility of lipid emulsions and intravenous drugs is the combination of these methods.²⁰ One of the important factors what is considered to determine the emulsion stability is the pH, since the H⁺ ions can alter the droplet charge by adsorption to the surface.

The emulsifier component in all three propofols, beside sodium oleate or oleic acid, is the egg-yolk lecithin which is a mixture of various phospholipids (PLs). Phosphatidylcholine and phosphatidylethanolamine are the major components which are unionised at pH 6–8. Other PLs of lecithin such as phosphatidylserine and phosphatidylglycerol are negatively charged at this pH, ensuring negative electrostatic repulsive forces.¹⁸ pH below 5 should be avoided, because the electrostatic repulsion between oil droplets is decreased resulting in the instability of the emulsion.²¹ In another study the cut-off value of pH of propofol was 3.5, as lower values resulted in increased instability.²² The optimum pH of the finished emulsion is considered to be 6–7.²³ Before sterilisation small amounts of sodium hydroxide can be used to adjust the pH to be around 8. A slightly alkaline pH is required because the

pH decreases during sterilisation, and on storage, due to the hydrolysis of glycerides and phosphatides which liberates free fatty acids.²³

The average size of the oil droplets of emulsions for intravenous delivery is 0.150 – 0.300 µm and the optimal size is generally considered ≤ 1 µm¹⁸. Our investigated formulae of propofol had smaller droplet size compared with the results of Stucki *et al.*, where the droplet size of the other propofol formula (Disopirovan, AstraZeneca) was 0.160 to 0.190 µm.²² It is known that the presence of monovalent or divalent cations can destabilise emulsions by neutralising the repulsive negative charges on the droplet surfaces leading to the physical instability of emulsions. It is often manifested in change of droplet size, ultimately leading to flocculation, coalescence or emulsion breaking. There was no difference in magnesium concentration, when the magnesium was added as a secondary additive to 0.9% sodium chloride or to other crystalloids. We expected, beside the equal magnesium concentration (4 mg/ml), that the globe size would be influenced by pH and by the other electrolyte compounds of crystalloids. In spite of this, only the propofol of FK showed a slight increase in the droplet size. Although, the highest change in droplet size was in many FK samples, but it is not considered clinically relevant. In the clinical practice the infusions are only mixed in a brief line segment during administration through a Y-site, consequently the contact time between the fluid layers is unlikely to exceed the 2 hours. We did not analyse the emulsions quantitatively, (e.g. HPLC), but we could not find any difference in the ingredients of propofol emulsions according to their summary of product characteristics. We measured the zeta potential of three original propofol only, but we did not find significant difference between them, which can explain our results. The zeta potentials of propofol emulsions are the following: FK -42,5 mV, BB -40 mV, UAB -44,4 mV. Therefore, we agree with the assumption of Zbytovska *et al.*, who state that, the stability of these mixtures can be influenced by the buffering capacity of the preparations.²⁴

MCTs can improve the stability of lipid emulsions by displacing LCTs at the droplet surface and reducing stress on the emulsifier due to the shorter hydrocarbon chain.²⁵ This change in the emulsion formulation could be the explanation, why we did not observe incompatibility when MCT/LCT propofols were

mixed with magnesium despite of similar magnesium concentrations were found to be incompatible with LCT propofol.²²

CONCLUSION

The practice of safe infusion administration is necessary particularly when simultaneous infusions are to be co-administered. The critically ill patients are exposed to a higher likelihood of medication incompatibility because of a high number of drug combinations. This study showed that the investigated MCT/LCT propofol injectable emulsions are physically compatible with 10% magnesium-sulphate, 10 % potassium-chloride and different composition crystalloids (0,9% NaCl, Isolyte, Ringerfundin, Sterofundin B, Sterofundin G) during a two-hour period. In the clinical practice, administration of these combinations via Y-site are safe.

What this paper adds

What is already known on this subject

- In the literature there are many chemical and physical compatibility data on LCT propofol in combination with often co-administered medications through the same infusion system.
- It is known that the presence of monovalent or divalent cations can destabilise emulsions by neutralising the repulsive negative charges on the droplet surfaces, leading to the physical instability of emulsions.

What this study adds

- This study displays the physical compatibility of several clinically relevant combinations of MCT/LCT propofol with commonly used crystalloids and electrolytes in the intensive care units.
- The co-administration of MCT/LCT propofol with the tested crystalloids through the same infusion line is safe.
